2017

I dedicate this work to my loving grandmother and my beautiful wife for their commitment to my success.

## **ACKNOWLEDGMENTS**

All praise and adoration is due to Almighty God for his mercy and blessings to see me through the journey of my M.Sc. study. I seek the peace and mercy of Almighty Allah upon the noble prophet Muhammad.

I will like to appreciate my family for their support during this period especially my wife for standing by me and encouraging me. I want to say a big thank you for my supervisor Dr. Mamdouh Al-Harthi for his fatherly role, believing in me and providing me more insight to horn my research skills. I want to appreciate my awesome committee for their contribution towards the completion of this work. I appreciate my friend Musa Najimu for his continuous words of encouragement. I want to also acknowledge the Nigeria community, NCUPM, at KFUPM for their support. I will like to further acknowledge the department of Chemical Engineering, KFUPM for their great faculty members and staff for their enormous support.

Lastly my appreciation goes to KFUPM and the kingdom of Saudi Arabia for providing me the privilege and platform to complete a graduate study. All in all, thank you everyone for being part of this beautiful phase of mine.

## ABSTRACT

Full Name : Taye Saheed Kazeem

Thesis Title : **LDHs Based Nanosorbents For Removal of Anionic Dyes**

Major Field : Chemical Engineering

Date of Degree : December 2017

Dyes are continuous global demanded products and are majorly disposed in water bodies; thus, the treatments of such pollutants are major challenges. Adsorption among various treatment options is affordable and available which endear its use by researchers and treatment plants. Of the various adsorbents used and reported, layered double hydroxides (LDHs) has been found to possess outstanding properties such as high surface area and excellent ion exchange capacities as well as ease of synthesis and regeneration.

The focus of this work lies on the synthesis of Ternary layered double hydroxide, NiMgAl (NMA) and MgCoAl (MCA) LDH, and their graphene based nanocomposites (G/NMA and G/MCA) via coprecipitation technique. These nanomaterials and their calcined products NiMgAl LDO (NMA-C), MgCoAl LDO (MCA-C), Graphene-NiMgAl LDO (G/MCA-C) and Graphene-NiMgAl LDO (G/NMA-C) were then used for the removal of an anionic dyes, Eriochrome Black T (EBT) and Methyl orange (MO), from aqueous solution. The adsorption processes were studied through isotherm, kinetic and thermodynamic investigations of various parameters such as initial solution pH, contact time, adsorbent dosage, initial dye concentration and temperature. All the adsorbent samples exhibit fast sorption optimized at acidic pH due to abundance of oxygen containing functional groups. The adsorption processes were suitably fitted by Langmuir isotherm with maximum adsorption computed to be 384.62 mg/g for EBT adsorption on G/NMA-C

and 434.78 mg/g for adsorption of MO on G/NMA-C. The highest capacities obtained for the calcined graphene nanocomposites arise from the synergistic contribution of graphene integration and calcination.

Furthermore, kinetics evaluation showed the suitability of pseudo-second order model which is due to the chemisorption nature of the adsorption process. Thermodynamics study has revealed the exothermic nature of the adsorption processes. High removal efficiency of the dyes with better recovery and reusability of these nanomaterials has highlighted their potential application in toxic water remediation. |

## ملخص الرسالة

الاسم الكامل: تايي سعيد كاظم

عنوان الرسالة: LDHs استنادا نانو المواد الماصة لإزالة الأصباغ الأنيونية

التخصص: هندسة كيميائية

تاريخ الدرجة العلمية: كانون الأول 2017

لأصباغ هي منتجات مطلوبة عالمية مستمرة ويتم التخلص منها بشكل رئيسي في المسطحات المائية. وبالتالي ، فإن معالجات هذه الملوثات تشكل تحديات رئيسية. الامتزاز بين خيارات العلاج المختلفة هو بأسعار معقولة ومتاحة والتي تحرص على استخدامها من قبل الباحثين ومحطات العلاج. من مختلف المواد الممتزة المستخدمة والمبلغ عنها ، تم العثور على هيدروكسيد مزدوج الطبقات (LDHs) يمتلك خصائص بارزة مثل مساحة السطح العالية والقدرات الممتازة للتبادل الأيوني وكذلك سهولة التجميع والتجديد.

ينصب تركيز هذا العمل على توليف هيدروكسيد مزدوج الطبقات الثلاثية ،  $\text{NiMgAl}$  (NMA) و  $\text{MgCoAl}$  LDH (MCA) ، ومركباتها النانوية المعتمدة على الجرافين ( $\text{G} / \text{MCA}$  و  $\text{G} / \text{NMA}$ ) عن طريق تقنية الترسيب. تم بعد ذلك استخدام هذه المواد النانوية ومنتجاتها المكلسة ( $\text{NiMgAl LDO}$  (NMA-C) ، و  $\text{MgCoAl LDO}$  (MCA-C) ، و  $\text{Graphene-NiMgAl LDO}$  (G / MCA-C) ، و  $\text{Graphene-NiMgAl LDO}$  (G / NMA-C)) لإزالة الأصباغ الأنيونية ، اريوتشروم بلاك تي (EBT) وبرتقال الميثيل (MO)، من محلول مائي. تمت دراسة عمليات الادمصاص من خلال تحليل متساوي للحرارة والحركية والديناميكا الحرارية لمختلف العوامل مثل درجة الحموضة الأولية ، وقت التماس ، الجرعة الممتزة ، تركيز الصبغة الأولي ودرجة الحرارة. تظهر جميع العينات الممتازة امتصاصاً سريعاً محسناً عند الأس الهيدروجيني الحمضي بسبب وفرة الأكسجين المحتوية على مجموعات وظيفية. تم تجهيز عمليات الامتزاز بشكل مناسب من قبل متساوي الساق لانجميور مع الحد الأقصى من الامتزاز المحسوب ليكون 384.62 ملغم / غرام من أجل امتصاص EBT على  $\text{G} / \text{NMA-C}$  و 434.78 ملغم / جم من أجل امتزاز MO على  $\text{G} / \text{NMA-C}$ . أعلى القدرات التي تم الحصول عليها لمركب نانوي الجرافين المكلس تنشأ من المساهمة التآزرية لتكامل الجرافين والتكليس.

وعلاوة على ذلك ، أظهر تقييم حركية مدى ملاءمة نموذج الطلب الثاني الزائف الذي يرجع إلى طبيعة امتصاص كيميائي لعملية الامتزاز. كشفت دراسة الديناميكا الحرارية الطبيعية الطاردة للحرارة لعمليات الإدمصاص. وقد أبرزت كفاءة إزالة الأصباغ العالية مع تحسين الاستعادة وإعادة القابلية لهذه المواد النانوية إمكانية تطبيقها في معالجة المياه السامة.

# **CHAPTER 1**

## **INTRODUCTION**

More than 700,000 tonnes of dyes are produced worldwide and about 15% of them find way into water bodies as effluents [1, 2]. Azo dyes are one of the world most demanded product due to their extensive use in textiles, printing, paints, plastic and they account for more than 60% of total world dye usage [3]. Organic pollutants are one of the major contributor to the bio-toxic, carcinogenic and anti-aesthetic threats facing human, atmosphere, and hydrosphere existence [4]. The output of these pollutants has been at alarming rate in recent years and there is need for development of abatement schemes to mitigate these daring effects. Wastewater mostly houses dyes at the end of the process. Since time immemorial, dye wastewater treatment and purification has always proven to be an arduous task.

Attempt to mitigate the quantity of these toxic discharge to the environment has led to deployment of treatment schemes such as solvent extraction, ion-exchange, membrane filtration, evaporation, etc. for waste water treatment. These different techniques have relative advantages but their drawbacks such as being expensive, availability, generation of secondary waste as well as regeneration/recyclability has generated concerns. Adsorption processes has shown promises to overcome these challenges with merits such as facile operation, affordability, availability, and efficiency[5-9].

For efficient performance in adsorption, selection and fabrication of the right adsorbent is critical. Adsorbents to be considered should be environmentally-friendly, affordable, stable and efficient. Despite numerous studies involving adsorption of contaminants from wastewater, the development of adsorbents who are highly recyclable, cheaply fabricated and have high adsorption capability accompanied by high specific surface area is a pivotal topic[10].

Recently, layered double hydroxides (LDHs), also termed as hydrotalcites, has seen huge applications in adsorption processes due to their exceptional ion exchange capacity [11, 12]. LDHs has also been explored in biomedicine, catalysis, magnetization, polymerization, electrochemistry, wastewater treatment, electronics and supercapacitors [12-16].. Furthermore, regeneration and reuse of the spent adsorbent is easy and its performance is comparable with unused LDHs adsorbent[10].

## **1.1 Aim of Study**

This thesis aims at application of LDHs based Nano-sorbents and its nanocomposites for the removal of anionic dye such as Eriochrome Black T (EBT) and Methyl orange (MO) and investigate various factors influencing the dyes adsorption for optimum performance.

## **1.2 Objectives**

Significant studies have gone into studies and applications of LDHs but a lot more still needs to be done. Specifically, we need to further explore the deployment of LDHs in the elimination of anionic dyes from aqueous phases as well as optimizing the factors needed

for efficient removal. To accomplish this, the objectives for this MSc research are highlighted below:

- (1) Synthesis of ternary LDHs and Graphene/ternary LDH nanocomposites.
- (2) Characterization of the as-synthesized adsorbents.
- (3) Study the performance of ternary LDH in removing EBT and MO from aqueous solution.
- (4) Study the efficiency of use of Graphene/ternary LDH nanocomposite in removing EBT and MO from aqueous solution.
- (5) Determination of appropriate kinetic models describing the adsorption of the dye.
- (6) Determination of appropriate adsorption isotherm describing the adsorption of the dye.
- (7) Determination of adsorption mechanism of the dye on the LDHs
- (8) Regeneration and reuse of adsorbents |

## CHAPTER 2

### LITERATURE REVIEW

#### 2.1 Structural Features

LDHs derived from parent mineral  $\text{Mg}_6\text{Al}_2(\text{OH})_{16}\text{CO}_3 \cdot 4\text{H}_2\text{O}$  [15] is a member of the family of 2-D nanostructured anionic clays which possesses hydrotalcite morphology and characterized by a positively charged host and charge balanced by substitutable interlamellar anions (see **Fig 2.1**). LDHs possesses a unique structural formula of  $[\text{M}^{2+}_{(1-X)}\text{M}^{3+}_X(\text{OH})_2]^{X+}[\text{A}^{n-}]_{X/n} \cdot m\text{H}_2\text{O}$  [13] where  $\text{M}^{2+}$  represents the divalent cations such as  $\text{Mn}^{2+}$ ,  $\text{Ca}^{2+}$ ,  $\text{Co}^{2+}$ ,  $\text{Zn}^{2+}$ ,  $\text{Fe}^{2+}$ ,  $\text{Ni}^{2+}$ ,  $\text{Mg}^{2+}$  while the  $\text{M}^{3+}$  represents the trivalent cation such as  $\text{Fe}^{3+}$ ,  $\text{Al}^{3+}$  and the  $\text{A}^{n-}$  is the intercalating anions which can be  $\text{OH}^-$ ,  $\text{F}^-$ ,  $\text{NO}_3^-$ ,  $\text{Cl}^-$ ,  $\text{CO}_3^{2-}$  or  $\text{SO}_4^{2-}$  and  $n$  has been reported to lie between 0.22 and 0.33 [15, 17]. Apart from the  $\text{M}^{2+}/\text{M}^{3+}$  combination of LDHs, quaternary LDHs [18] as well as LDHs with monovalent lithium (with Aluminum as the trivalent cation) are available [19]. There have studies relating to the synthesis of  $\text{M}^{2+}/\text{M}^{4+}$  combination of LDHs. The range of possible combination of  $\text{M}^{2+}$ ,  $\text{M}^{3+}$  and  $\text{A}^{n-}$  as well as variation of ratio of  $\text{M}^{2+}$  to  $\text{M}^{3+}$  influence both the ion exchange capacity and charge density of LDHs give rise to different application of LDHs [20-22].

Due to excellent ionic exchange capability, various LDHs have been synthesized for the sorption of toxic materials. Partial and isomorphic substitutions of  $\text{M}^{2+}$  with  $\text{M}^{3+}$  result in excess positive charges which are balanced by interlayered water molecules and anions of

**Fig 2.1 Schematic diagram of LDHs**

the LDHs[23]. These excellent properties enable LDHs captures both inorganic and/or organic anions. Intercalation of large and highly charged anions into the structure of LDHs provides a great possibility of inducing the adsorption of cations. Heteropoly blue, a derivative of Polyoxometalate, with high negative charge was facilely incorporated by ion-exchange into ZnAl-LDH to eliminate methylene blue in the aqueous mixture [24]. Noticeable shift in the  $2\theta$  value is observed in the XRD pattern for a successful intercalation into the LDH structure [24].

## **2.2 Synthesis of LDHs**

LDHs can be facilely prepared through various methods as explained by He et al [25]. These are

### **2.2.1 Coprecipitation**

This involves using precursors of the divalent and trivalent cations to be incorporated into the LDH and preparing under supersaturation condition in order to simultaneously precipitate the cations. The coprecipitation can either be done at high supersaturation or low supersaturation. For high supersaturation, the mixed salt solutions of  $M^{2+}$  and  $M^{3+}$  is added to alkaline solution possessing the desired intercalated anion. Whereas for low supersaturation, the mixed salt solution is slowly added to the aqueous solution of the required interlayer anion during which alkaline solution is simultaneously added into the reacting mixture to adjust to pH needed for precipitation. Due to formation of larger amount of crystallization nuclei, coprecipitation at high supersaturation produces less crystalline samples compared to low supersaturation.

### **2.2.2 Rehydration/ Reconstruction**

This uses “memory effect” to obtain LDH from mixed metal oxide (MMO). Calcined LDHs, which yield MMO, have the potential to regenerate LDHs on exposure to H<sub>2</sub>O and anions[26]. The resultant LDH may also be different from the parent LDH if the introduced anion is different from the anion used in the initial synthesis, hence this is a novel way to synthesis desired LDH tailored for specific application

### **2.2.3 Nucleation and Aging technique**

This synthesis mode was proposed by Zhao et al.[27] in which crystallites formation involves both nucleation and aging and is characterised by rapid mixing. Crystallinity obtained is better than that of coprecipitation.

### **2.2.4 Ion Exchange**

This is applicable when coprecipitation is not feasible which may be due to instability of divalent cation or trivalent cation or anion in alkaline solution. It is also used when direct reaction involving the anion to be intercalated and the host metal is highly favoured. This results in a unique anion-pillared LDH[28]

### **2.2.5 Urea Hydrolysis**

This method have been used in a lot of work for LDHs synthesis [10, 29]. Urea is highly sort after due to its high-water solubility, weak bronsted base nature and facile control of hydrolysis rate.

### **2.2.6 Hydrothermal**

This is more appropriate for intercalating organic guest specie whose affinity is poor for LDHs and where coprecipitation and ion exchange are not feasible. The possibility that the intended organic anion will fill the interlayer position makes this method efficient[30].

### **2.2.7 Others**

one-pot in situ approach [31], Innovative aerogel, fast coprecipitation followed by controlled hydrothermal treatment, secondary intercalation, template synthesis, surface synthesis, salt-oxide method and much more [25]

## **2.3 Characterization of LDHs**

### **2.3.1 FTIR Spectroscopy Analysis**

LDHs are characterised by a variety of vibration which may consist of bending, symmetric stretching and antisymmetric stretching modes of the interlayer water molecules; bending, torsion, symmetric stretching and antisymmetric stretching modes of the carbonate group; stretching modes of the metal-hydroxyl ion bond (M-OH) as well as vibrations of the metal-metal bond (M-M). Usually the peaks between  $3200\text{--}3800\text{ cm}^{-1}$  is associated with the stretching vibrations of OH group of interlayer  $\text{H}_2\text{O}$  as observed for the 3 calcined LDHs in Zubair et al. [32]. Peaks around  $1500\text{--}1700\text{ cm}^{-1}$  corresponds to bending vibrations of OH in water molecules while peaks around  $1300\text{--}1500\text{ cm}^{-1}$  indicates antisymmetric vibrations associated with C=O of carbonate group[33]. Other peaks associated with carbonate are located around  $1000\text{--}1100\text{ cm}^{-1}$  (bending non-polar mode),  $800\text{--}900\text{ cm}^{-1}$  (torsion mode),  $600\text{--}700\text{ cm}^{-1}$  (bending angular mode) [33]. (check notebook to locate reference). The M-O-M, M-O and O-M-O peaks are found below  $1000\text{ cm}^{-1}$ [32].

### **2.3.2 X-Ray Diffraction (XRD) Analysis**

XRD pattern of LDH are characterized by typical reflection peaks 003, 006, 009, 110 and 113 spectrums as shown in Fig 2.2. Intense diffraction peak is an indication of good crystallinity while a lower peak indicates poor crystallinity [32, 33]. For composites, which may involve physical deposition of extra specie on the LDH such as  $\text{Fe}_3\text{O}_4/\text{ZnCr-LDH}$  composite [34], the reflection peaks may not be change obviously when compared to the individual component.

### **2.3.3 Scanning Electron Microscopy (SEM)**

The morphology, size and composition of LDHs can be explicitly shown by SEM. ZnAl-LDHs of molar ratio of Zn/Al equals 2 displays a hexagonal platelet morphology which changes to a 3D “silk flower-like” structure on using water–n-BuOH as solvent for synthesis instead of the initially used water [35]. The ZnAl-LDHs morphology was also earlier shown in the work of Zhang et al. [36]. As-synthesized MgAl-LDHs shows hexagonal platelet structure which transforms to a blossom sphere on incorporation of Zn to form ZnMgAl-LDHs [37]. The perfect blossom spherical configuration of the ZnMgAl-LDHs reduces with increase in the Zn/Mg until it almost vanishes at a ratio of 0.8. Zubair et al. [32] reported CoAl-LDHs to display cotton-like agglomerates while MgAl shows irregular cubical morphology while NiFe shows a coarse, rutted flowered like particles.

**Fig 2.2 Sample XRD of LDHs**

**Fig 2.3 Sample FTIR of LDHs**

### 2.3.4 BET-Analysis

This analysis involves documentation of the corresponding pore size distributions (PSD) of the adsorbent carried out by nitrogen adsorption-desorption with a. As shown in table 2.1, LDHs possess high specific surface area. More importantly, calcination improves the specific surface area of LDHs, hence an increase in adsorption capacity. Furthermore, hybrid nanocomposites are characterized by higher surface area and individual components

## 2.4 Adsorption Mechanism

The mechanism behind adsorption of adsorbates on LDHs adsorbents covers a wide range from ion exchange[38], to electrostatic attraction and chemical/ hydrogen bond between the adsorbent and adsorbate[32]. Also, chemisorption has been reported as the mechanism in the work of Zhi-qing Zhang et al.[29] in the adsorption of Cr(VI). Yasin et al. [39] explained that the mechanism behind  $Pb^{2+}$  removal from aqueous solution was surface precipitation reaction for Mg–Al LDH while complex formation was responsible for tartrate intercalated Mg–Al LDH removal of  $Pb^{2+}$ . Isomorphic substitution was proposed as one of the possible mechanism for adsorption in removal of Cu(II) during the simultaneous removal of Cr(VI) and Cu(II) ions from aqueous solution[40]. Due to isomorphism between Mg and Cu(II), Cu(II) who possesses slightly larger ionic diameter substituted into the brucite-structure thereby increasing the basal spacing of the resultant LDH. Other removal mechanisms is the work were anion-exchange, precipitate formation of  $Cu_2Cl(OH)_3$ , and adsorption of Cr(VI) by  $Cu_2Cl(OH)_3$ .

For anionic Congo Red dye removal using MgAl-Cl LDH, Lafi et al [41] reported surface adsorption as the mechanism as no shift in the ray spectrum of Congo Red adsorbed on LDH (MgAl–LDH-CR) when compared with the MgAl-LDH

**Table 2.1 BET Surface Areas of Various LDHs**

| LDHs                                 | Surface Area<br>(m <sup>2</sup> /g)                     | Pore Volume<br>(mL/g) | Reference |
|--------------------------------------|---|-----------------------|-----------|
| MgAl                                 | 24.74 (uncalcined)<br>165.07 (calcined)                 | ---                   | [42]      |
| TiO <sub>2</sub> / ZnAl              | 37.3 (ZnAl)<br>153.6 (TiO <sub>2</sub> / ZnAl)          | ---                   | [31]      |
| Fe <sub>3</sub> O <sub>4</sub> /ZnCr | 45 (ZnCr)<br>114 (Fe <sub>3</sub> O <sub>4</sub> /ZnCr) | ---                   | [34]      |
| NiAl                                 | 205.76 (calcined)                                       | 0.4139                | [43]      |
| ZnMgAl                               | 82.13   | ---                   | [37]      |
| Fe <sub>3</sub> O <sub>4</sub> /ZnCr | 185.20  | ---                   | [44]      |

## 2.5 Effects of Various Parameters on Adsorption

### 2.5.1 pH

The contribution of pH on the removal efficiency of adsorbents ranges from no effects, increasing adsorption to decreasing adsorption with increase in initial pH of the solution. This is due to the fact that pH influences the adsorbent surface charge as well as the degree of ionization of adsorbate [41, 45]. An important factor to consider is the pH at Point of zero charge ( $pH_{pzc}$ ). Considering  $pH > pH_{pzc}$ , LDH surface has a resultant negative charge, which leads to repulsion of the anionic dyes by the LDHs but this favours the adsorption of positive dyes. For  $pH < pH_{pzc}$ , a positively charged LDH results which favors adsorptions of anionic dyes while unfavourable adsorption occurs for cationic dyes. However, very small value of pH,  $pH \ll pH_{pzc}$ , the LDH becomes impaired resulting in instability and this reduces the adsorption of anionic dyes. At very high pH ( $pH \gg pH_{pzc}$ ), increasing competition of  $OH^-$  adsorption for active adsorption sites reduces the adsorption of anionic dyes [15].

For study involving adsorption of Congo red in aqueous medium by MgAl-LDH, the amount removal increases insignificantly with pH increase (in range of 2.7 to 10.2) [41]. This was due to the buffering capability of the LDHs [46, 47]. Beyond this buffering pH range, the adsorption capacity of LDH reduces because of electrostatic repulsion between adsorbate and adsorbent and/or competition between the anionic adsorbate and  $OH^-$  for the active adsorption sites.

In the study of Shan et al. [33], no effect of pH increment on one of the dyes (RR) whereas for the other two (CR and AR1), the adsorption varied negligibly with pH from 2-10 after

which there was a sharp decrease in adsorption with increase in pH. The chemistry between the adsorbent and dye molecules is affected by pH of dye solution. For the study of Yang and his team, the adsorption capacity increases as the pH increases from 2 until a maximum pH of 5[48]. Also, as at the maximum pH, the adsorption performance of the LDHs is greater than the individual building units due to synergistic effects. In addition, the calcined LDH has higher adsorption performance than the noncalcined counterpart. Adsorption quantity of EBT with increased in pH for all the three LDHs considered in the work of Zubair et al. [32]. This was associated with reduced electrostatic attraction between anionic dye EBT and LDH at higher. The same report was earlier presented by Yasin et al. [49]

Decreasing adsorption with increasing pH was reported in removal of methyl orange by calcined NiAl-LDH. It was proposed that at low pH, the large number of positive charged binding sites on the NiAl-LDH (due to protonation) electrically attract the anionic MO and with increased pH electrical repulsion sets in thereby reducing adsorption.

### **2.5.2 Contact Time**

Contact time is a significant parameter to consider in the interaction between contaminants/pollutants and adsorbents. In general, adsorption increases with contact time until equilibrium is attained. The equilibrium time greatly depends on the factors such as composition/ type of LDH, the precursors used for the synthesis, the adsorbent dosage and initial dye concentration. According to Ahmed and Gasser [50], an approximate equilibrium time of 15 minutes is needed for removal of about 98 % of Congo Red by MgFe-CO<sub>3</sub> using 0.003 g/mL adsorbent dosage in a 100 mg/L Congo Red solution

Equilibrium times of 20 and 140 minutes were reported for initial dye concentrations of 20– 80 mg/L and 120–160 mg/L respectively indicating an increase in equilibrium time with increased initial dye concentration[41].

### **2.5.3 Initial Solution Concentration**

This effect varies from one LDH to the other. It was reported that the adsorption at equilibrium increased from 8 to 65 m/g for an increase in initial dye concentration from 20 to 160 mg/L[41]. For the case on Methylene orange adsorption on ZnMgAl-LDH, degree of removal of the dye reduces on increasing the initial dye concentration from 0.07 to 0.12 g/L [37]. This was due to reduction in active sites for MO adsorption

### **2.5.4 Adsorbent Dosage**

The amount of adsorbate removed (removal efficiency) from an aqueous solution generally increases with adsorbent dosage [51]. From the study of Shan and his group[33], the removal of the adsorbates (the 3 red dyes) increased with increase in adsorbent dosage until an equilibrium is attained. Though the removal efficiency for methylene orange increased with increase in adsorbent dosage but it was reported that a decrease in adsorption capacity reduced (from about 520 to 44.32 mg/g) with increasing adsorbent dosage (2.5 to 30mg) by biomorphic MgAl-LDH [52]. The increase in removal efficiency of the dye was attributed to increase in number of adsorption sites [49].

### **2.5.5 Thermodynamic Study and Temperature**

Thermodynamic parameters are indicators of spontaneity and feasibility of adsorption processes. The significance of temperature on adsorption is studied through change in standard free energy ( $\Delta G$ ), change in entropy ( $\Delta S$ ) and change in enthalpy ( $\Delta H$ ) which are

extracted from experimental data at various temperature using the following relations [50]

$$\Delta G = -RT \ln K_D \quad 2.1$$

$$\ln K_D = \frac{\Delta S}{R} - \frac{\Delta H}{RT} \quad 2.2$$

$K_D$  defines distribution coefficient,  $T$  is absolute temperature and  $R$  is molar gas constant.

$\Delta H$  and  $\Delta S$  relationships with  $\Delta G$  is expressed are expressed according to the following equations [43].

$$\Delta H = -R \left( \frac{T_2 T_1}{T_2 - T_1} \right) \ln \frac{K_1}{K_2} \quad 2.3$$

$$\Delta S = \frac{\Delta H - \Delta G}{T} \quad 2.4$$

$K_2$  and  $K_1$  are the Langmuir constants  $T_2$  at and  $T_1$  respectively. A positive  $\Delta H$  indicates endothermic reaction while negative value denotes exothermic process. A positive  $\Delta S$  indicates increased randomness of adsorption process. A negative  $\Delta G$  depicts the spontaneity of the process [41].

The influence of temperature is determined nature of heat change involved on the adsorption process which can either be endothermic or exothermic. For an endothermic adsorption system, the amount of adsorbate removed by the adsorbent increases with increasing temperature as was observed in methyl orange (MO) adsorption by calcined NiAl-LDH [43]. The converse happens for exothermic adsorption system which involves decrease in adsorption by adsorbent with increasing temperature.

### 2.5.6 Coexisting ions

Several articles have been published showing influence of coexisting ions on adsorption by LDHs and also its composites [45, 53-55]. The coexisting ions may improve adsorption of the specie of concern on the LDH. This case was reported for Methylene blue (a cationic dyes) removal from aqueous solution in the presence of anionic components with higher removal capacity ( $\text{HPO}_4^{2-} > \text{SO}_4^{2-} > \text{Cl}^-$ ) [45]. The converse of inhibiting adsorption occurs for the case of competing ions. For As(V) adsorption on LDHs, interference of competing ions follows the order  $\text{HCO}_3^- > \text{HPO}_4^{2-} > \text{SO}_4^{2-} > \text{Cl}^-$  while that of As(III) follows  $\text{HPO}_4^{2-} > \text{SO}_4^{2-} > \text{CO}_3^{2-} > \text{F}^- > \text{Cl}^- > \text{Br}^- > \text{NO}_3^-$  [15]. In industrial application, wastewater contains coexisting ions which will always compete for adsorption sites.  $\text{CO}_3^{2-}$ ,  $\text{SO}_4^{2-}$ ,  $\text{H}_2\text{PO}_4^-$  and  $\text{Cl}^-$  will always strongly compete with Cr(VI). 85.0%, 75.0%, 24.2%, and 13.3% reduction in adsorption of was recorded on Cr(VI) was recorded in the presence of 20 mmol/L of  $\text{CO}_3^{2-}$ ,  $\text{SO}_4^{2-}$ ,  $\text{H}_2\text{PO}_4^-$  and  $\text{Cl}^-$  respectively [10]

## 2.6 Adsorption Isotherm

Adsorption isotherm is an indication of extent of distribution of adsorbate between the solid phase and liquid phase upon reaching equilibrium in the adsorption process. Two of the well-established isotherms are the Langmuir and Freundlich isotherms. Among other isotherms belongs the Sips [56], Temkin [57], Redlich–Peterson [43], Dubinin–Radushkevich [58] .The Langmuir isotherm which is based on monolayer adsorption assumes homogeneous adsorption sites possess with equal energy [59] and non-linear form is given by

$$q_e = \frac{q_m b C_e}{1 + b C_e} \quad 2.5$$

In linear form, equation 2.3 is expressed as

$$\frac{C_e}{q_e} = \frac{1}{b q_m} + \frac{C_e}{q_m} \quad 2.6$$

Where  $q_e$  is quantity of dye adsorbed (mg/g),  $C_e$  is amount of dye adsorbed at equilibrium (mg/L) and the langmuir constants  $q_m$  (mg/g) and  $b$  (L/mg) are the maximum monolayer adsorption of the adsorbent and relation to free energy of adsorption respectively[41]. A consolidating parameter to determine the favourability or non-favourability of the adsorption system is the essential factor (or equilibrium parameter or separation factor),  $R_L$  defined by Chen et al.[60] as

$$R_L = \frac{1}{1 + b C_0} \quad 2.7$$

Where  $R_L > 1$ ,  $R_L = 1$ ,  $0 < R_L < 1$  and  $R_L = 0$  indicate unfavourable, linear, favourable, and irreversible adsorption.  $C_0$  is the highest initial dye concentration (mg/L)

Freundlich isotherm, which is appropriate for low concentration, assumes a heterogeneous surface with heat of adsorption distribution [43] and mathematically represented as

$$q_e = K_F C_e^{1/n} \quad 2.8$$

Equation 2.6 can also be converted to linear form as given in equation 2.7

$$\log q_e = \log K_F + \frac{1}{n} \log C_e \quad 2.9$$

$C_e$  and  $q_e$  retains the same definition as previously defined.  $n$  and  $K_f$  are Freundlich constants in which  $n$  indicates the extent of nonlinearity between adsorption and

concentration of solution and provides information on favourability of adsorption while  $K_f$  ( $\text{mg}^{1-1/n} \text{L}^{1/n} \text{g}^{-1}$ ) shows degree of adsorption.

Redlich-Peterson (RP ) isotherm is a 3-parameter model that combines Langmuir and Freundlich isotherms [61]. The relation approaches Langmuir isotherm at low concentration and Langmuir at high concentration. RP isotherm is defined as

$$q = \frac{A p}{(1 + B p^g)} \quad 2.10$$

Temkin isotherm [62] considers the adsorbate- adsorbent interaction where the heat adsorption reduces linearly with coverage for all molecules. In nonlinear and linear forms it is represented respectively as

$$q_e = B \ln(A C_e) \quad 2.11a$$

$$q_e = B \ln A + B \ln C_e \quad 2.11b$$

and B is defined by

$$B = RT/b_T \quad 2.12$$

$1/b_T$  defines the adsorbent adsorption potential T and R stands as previously defined. In the  $q_e$  versus  $C_e$ , there will be a linear reduction in energy of adsorption as adsorption sites are occupied. There is linear decrease in heat of adsorption with surface coverage because of adsorbate-adsorbent interaction. There is also an assumption that there is homogeneous distribution of binding energy to peak during the adsorption.

## 2.7 Adsorption Kinetics

Pseudo-first order and pseudo-second order are the prominent models used to predict sorption process mechanism[63]. The pseudo-first order model (named as Lagergren's pseudo-first-order model) which considers diffusion through a boundary layer prior before adsorption is given as

$$\log(q_e - q_t) = \log q_e - \frac{k_1 t}{2.303} \quad 2.13$$

Where  $q_t$  is time-dependent amount of dye adsorbed per unit of adsorbent (mg/g) during time contact time  $t$  (min),  $k_1$  is the pseudo-first order rate constant ( $\text{min}^{-1}$ ).  $k_1$  is obtained from the plot of  $\log(q_e - q_t)$  versus  $t$ . The pseudo-second order model is as follows  $k_2$  is the pseudo-second order rate constant ( $\text{g mg}^{-1} \text{min}^{-1}$ ).

$$\frac{t}{q_t} = \frac{1}{k_2 q_e^2} + \frac{t}{q_e} \quad 2.14$$

One of the parameters to determine which model to choose is the statistical tool correlation co-efficient ( $R^2$ ). The high  $R^2$  shows strong correlation between the model and experimental data, hence the model with the highest  $R^2$  will be considered as the appropriate model to depict the experimental data. In most of the studies a  $R^2 > 0.97$  provides high confidence in the model considered.

## 2.8 Impact of Calcination and Adsorption Temperature

Calcination affects the structure, texture and performance of LDHs. The thermogravimetric analysis (TGA) of Ni-Al LDH shows three regions of weight loss [43]. The first (below  $230^\circ\text{C}$ ) is associated with loss of physisorbed as well as interlayer  $\text{H}_2\text{O}$  molecules [64]. The second region (between  $230^\circ\text{C}$  and  $500^\circ\text{C}$ ) indicates removal of  $\text{NO}_2$  and  $\text{OH}$  from the

interlayer anions and brucite structure respectively. Beyond the region 2 (above 500<sup>0</sup>C), no further weight loss and phase change was observed. This was further corroborated by DTG which shows total breakdown of the LDH at 345<sup>0</sup>C. The resultant specie is a mixed metal oxide (MMO)

In the work Zhi-qing Zhang et al.[29], he reported the XRD analysis that the characteristic reflection of LDHs at (003), (006) and (009) becomes weak and increased production of reflection at (200) and (300) associated with MgO as calcination temperature is increased. These observed weak reflections at 300<sup>0</sup>C and 400<sup>0</sup>C imply the layered are maintained but there is a resultant dehydration and dehydroxylation [65]. At higher temperatures (500<sup>0</sup>C and above), the reflections associated with LDH disappeared and those associated with typical mixed metal oxide (MgO) becomes visible.

In the same work of Zhi-qing Zhang et al.[29], the group showed that at the 300<sup>0</sup>C calcination temperature, the peak at 1630 cm<sup>-1</sup> was visibly absent as a result of elimination of interlayer water molecules. Also the reduction of peak intensities at 1054, 1384 and 1560 cm<sup>-1</sup> from 300<sup>0</sup>C to 400<sup>0</sup>C was due to continuous elimination of CO<sub>3</sub><sup>2-</sup> and peak associated with CO<sub>3</sub><sup>2-</sup> completely vanished for calcination temperature of 500<sup>0</sup>C implying a complete destruction of the hydrotalcite configuration. It becomes interesting to note an impure MgAl<sub>2</sub>O<sub>4</sub> phase is formed upon calcination at 600<sup>0</sup>C.

According to SEM analysis in the work of Zhi-qing Zhang et al.[29], calcination temperature greatly affected the textural properties of the LDHs. The pore volume (PV) and specific surface area (SSA) increase with temperature (a maximum of 500<sup>0</sup>C) after which a decline of these properties occurs at 600<sup>0</sup>C due to for formation of impure phase

MMO (agglomeration and sintering occurrence). The pore size was not significantly affected by calcination.

## **2.9 Regeneration and Recovery of LDHs**

Regenerating LDHs adsorbents is one of the key economic parameters to be considered in the industrial feasibility of the use of LDH. Various studies have been performed on the regeneration mode using reagents such as sodium carbonate, mineral acids, ammonia solution, mineral acids as well as combustion. Organics-laden LDHs can be combusted at relatively high temperature to completely remove the adsorbates [66]. Ahmed and Gasser [50] combusted Mg–Fe–Dye–LDH for 2 hours to completely alienate Congo red from the adsorbate. Carbonate and chloride solutions could help regenerate oxyanion-laden LDHs [15]. Bacteria culture have been used to regenerate Methylene blue loaded LDH and this improved the adsorption capacity of the LDH on the first regeneration cycle through synergistic effects [45]. Acetone extraction along with drying was used in the recovery ZnAl–PW<sub>10</sub>Mo<sub>2</sub> LDH after its adsorption of Methylene blue [24]. It is worthy of note to report that second adsorption cycle yielded a poor 33% which may be of economic viability though it was indicated that the poor result may be due to partial extraction of the adsorbate from the adsorbent.

After several cycles of regeneration of LDHs, the adsorption capacity of the LDH will reduce and this may be due to reduction in crystallinity of the LDH [67], thus affecting its continuous use for adsorption purpose.

Recovery of LDH from water in industrial process is an arduous task, Yan et al.[68] synthesised a Fe<sub>3</sub>O<sub>4</sub> / LDH nanocomposite as a magnetic adsorbent of Ur(IV) ions from

water. This enables easy separation of the composite by a magnet after the adsorption process.

## CHAPTER 3

### EXPERIMENTAL AND METHODOLOGY

#### 3.1 Synthesis of LDHs and its Nano-Composites

The LDHs samples were all prepared by coprecipitation method. To prepare the nano-composite, ultrasonication was applied to ensure effective dispersion.

##### 3.1.1 Materials and Reagents

The following are the reagents used without further purification:

1. Nitrate salts:  $\text{Co}(\text{NO}_3)_2 \cdot 6\text{H}_2\text{O}$ ,  $\text{Ni}(\text{NO}_3)_2 \cdot 6\text{H}_2\text{O}$ ,  $\text{Mg}(\text{NO}_3)_2 \cdot 6\text{H}_2\text{O}$ , and  $\text{Al}(\text{NO}_3)_3 \cdot 9\text{H}_2\text{O}$  (all purchased from Sigma-Aldrich)
2. NaOH (from Panreac AppliChem, Darmstadt, Germany)
3. Acids: HCl (from Eurostar, Liverpool UK) and  $\text{HNO}_3$
4. Hydrazine
5. Ethanol
6. Graphene (GRAFEN®-SEG / Semi-exfoliated Graphene Sheets): diameter ~200  $\mu\text{m}$ , thickness < 50 nm
7. Deionized water

##### 3.1.2 Synthesis of Ternary LDHs and Graphene/ Ternary LDHs nanocomposites

The procedure was followed from the work of Zubair et al. [32] with slight adjustment. The preparation of NiMgAl LDH (NMA) is shortly described as follows. 0.02 mole of  $\text{Al}(\text{NO}_3)_3 \cdot 9\text{H}_2\text{O}$ , 0.02 mole of  $\text{Ni}(\text{NO}_3)_2 \cdot 6\text{H}_2\text{O}$  and 0.04 mole of  $\text{Mg}(\text{NO}_3)_2 \cdot 6\text{H}_2\text{O}$  (total ratio

of  $M^{2+}$  to  $M^{3+}$  is 3) were dissolved in 60 ml of deionized water in a 500-ml round bottom flask. The was stirred vigorously at 600 rpm in an oil bath at 60<sup>0</sup>C for 15 mins. Subsequently 1M NaOH was added dropwisely to stabilize the pH at  $10 \pm 0.5$  while maintaining the stirrer speed and temperature of 60<sup>0</sup>C. Thereafter, the temperature was raised to 90<sup>0</sup>C and stirring increased to 900 rpm while the reaction was refluxed for 24h. The suspension obtained was subjected to centrifugation and washed twice with deionized water and then followed by twice washing using ethanol to remove impurities. The densely-obtained slurry was dried in a vacuum oven at 90<sup>0</sup>C for 24-48h. In the synthesis of MgCoAl LDH (MCA), the same procedure outlined for NMA synthesis was followed with Ni substituted by Co and the molar ratio was maintained (Mg: Co: Al = 2: 1: 1)

As for graphene/ ternary LDHs nanocomposites, 300 mg of graphene was added to 60ml NaOH (0.2 M) and the mixture ultrasonicated at 60 rpm for 90 min. The obtained mixture was then added to a prepared mixture of the ternary LDHs precursor and two to three drops of hydrazine was added as a complexing agent. Other procedures were followed as outlined in the synthesis of NMA. Both ternary NMA and G/NMA were calcined at 400<sup>0</sup>C for 3h under 120 mL min<sup>-1</sup> N<sub>2</sub> environment to produce NMA-C and G/NMA-C respectively and stored for use in adsorption experiment. Likewise, MCA and G/MCA was subjected to calcination in similar manner to generate MCA-C and G/MCA-C respectively.

### **3.2 Characterization Techniques**

For excellent description of the as-synthesized samples, characterizing the LDHs and its nanocomposite samples was done by: (i) Scanning Electron Microscope Analysis (ii) X-Ray diffraction (XRD) (iii) FTIR spectroscopy and (iv) Thermogravimetry analysis. These are briefly explained below

### **3.2.1 XRD Analysis**

XRD is resourceful, non-destructive technique which shows comprehensive facts about the crystallographic and micro structure of all kinds of natural and synthetic materials. This method is applied in different sectors of life. In order to detect the crystallographic structure of catalyst samples, patterns of diffraction are employed. One essential drawback of this techniques is that non-crystalline phase(s) and minute particle(s) can give wide and feeble lines of diffraction and in some instances will give no line of diffraction. This occurrence will eventually make them practically undetectable to X-Ray Diffraction.

Powder X-Ray Diffraction (XRD) measurements will be considered to detect the crystallographic structure of the synthesized LDHs and its nanocomposite samples. The XRD diffraction patterns of the catalyst samples will be gotten by utilizing an MinifeFlex II instrument from Rigaku Instruments with a monochromatic Cu K $\alpha$  radiation source (wavelength = 0.15406 nm, 30 kV, 40 mA) and a normal scan rate of 3 scans per minute within the  $2\theta$  range of 5-70 degrees with a step size of 0.03

### **3.2.2 Scanning Electron Microscope Characterization**

The scanning electron microscope is a tool used for material characterization with the aim of obtaining information about the structure, composition and defects in materials. The images are obtained by scanning electron beam of high energy on the sample surface. The scanning electron provide information about surface topography, shape, size and structure of grains, failure analysis, and elemental distribution. It uses a spatial resolution of 1 nm and sampling depth of 1-5 $\mu$ m. It can be used to analyze sample of area of <1 to 100  $\mu$ m. It has detection limits of 0.2 wt%. It is generally applied for solid samples.

Each of the samples will be analyzed by the SEM while ensuring that the microscope is aligned to avoid lack of sharpness and focus. Other necessary precautions is to ensure large objective aperture in order to have low resolution, small depth of field, small smooth image and make it suited to micro-chemical analysis. An electron beam is incident across each catalyst sample resulting in the generation of secondary and back scattered electrons which are used to form images and X rays are used to obtain elemental constitution of the catalyst samples. This characterization will reveal the structure and elemental composition of all the five catalyst samples.

### 3.3 Adsorption Experiment

The adsorption experimental process was carried out to investigate and select the optimum process parameters need LDHs removal of anionic dyes. These are pH, adsorbent dosage, concentration of dye, temperature and contact time. From the data obtained, information on the appropriate kinetics, isotherm as well mechanism behind the adsorption process can be presented.

The percentage dye removal (%), time-dependent adsorption capacity ( $q_t$ ) and equilibrium adsorption capacity ( $q_e$ ) and are computed from the following equations

$$\% \text{ Dye removal} = \frac{C_o - C_e}{C_o} * 100 \quad 3.1$$

$$q_t = \frac{C_o - C_t}{M} * V_S \quad 3.2$$

$$q_e = \frac{C_o - C_e}{M} * V_S \quad 3.3$$

Where  $C_o$ ,  $C_e$ ,  $C_t$ ,  $V_s$  and  $M$  respectively represent initial concentration of dye solution (mg/L), equilibrium concentration of dye solution (mg/L), concentration of dye solution (mg/L) at time  $t$ , volume of dye solution used (mL) and weight of adsorbents (mg).

### **3.3.1 Determination of Optimum pH**

30ml of 30 ppm dye solution was placed in each seven 100 ml conical flask. The pH adjustment from 2 to 7 of each flask solution was carried with 0.1M HCl or 0.1M NaOH. 10 mg of as-prepared LDHs samples was subsequently added to the solution. These flasks were then put on a shaker and operated at 180 rpm for 24 h to enable establishment of equilibrium. Thereafter, the sample were centrifuged to obtain the supernatant and the solid residue. The supernatant was analysed using UV-Visible spectrometer under the area of maximum absorbance to determine the concentration of dye remaining.

### **3.3.2 Determination of Adsorbent Dosage Effect**

Upon determining the optimum pH needed to maximize adsorption, the influence of dosage of adsorbent is considered in the experiment. This is done by preparing a given concentration such as 30 ppm of dye solution in a 100ml conical flask and adjusting at the optimum pH using either 0.1M HCl or 0.1M NaOH. Different dosage of adsorbent: 5mg, 10mg, 15mg, 25mg, 40mg, 55mg and 70mg will be added to each flask and the flasks place on the shaker operated at 250 rpm for 24h to ensure equilibrium adsorption. The obtain samples are centrifuged and subsequently analysed for absorbance using UV-Visible spectrometer. The obtained data of absorbance versus dosage is tabulated, plotted and analysed to determine optimum dosage for the given concentration of dye solution

### **3.3.3 Determination of Effect of Dye Concentration**

This will be carried out at temperature of 25<sup>0</sup>C. 20-160 ppm of dye concentration will be prepared in 100ml conical flask and the pH adjusted to the optimal value. 10mg of the as-synthesized LDHs adsorbent will be added to each flask and the flask agitated on the shaker at 250 rpm for 24 h. The obtained samples are then centrifuged and the absorbance obtained. The obtained data is tabulated, plotted and analyse to determine the significance of dye concentration on the adsorption process.

### **3.3.4 Determination of Effect of Contact Time**

The dye removal efficiency expressed in terms of absorbance is being plotted at different concentration (20, 40 and 100 ppm) as a function of contact time (0-24 h). The procedure follows what has been previously outlined in 3.3.1 to 3.3.3 but additionally, the samples are prepared and analysed for absorbance at different contact time such as 5min, 10min, 15min, and so on until for 24 hrs.

## **CHAPTER 4**

### **Graphene/ Ternary Layered Double Hydroxide**

#### **Nanocomposites For Efficient Adsorption Of Eriochrome Black T**

##### **From The Aqueous Phase**

This chapter reports the result of sorption of Eriochrome Black T (EBT) from aqueous phase using ternary LDH and its nanocomposites. For simplicity of understanding uncalcined NiMgAl, calcined NiMgAl, uncalcined graphene-NiMgAl and calcined Graphene-NiMgAl are referred to as NMA, NMA-C, G/NMA and G/NMA-C respectively

#### **4.1 Characterization of NMA, G/NMA, NMA-C and G/NMA-C**

XRD patterns of the NMA, G/NMA, NMA-C, and G/NMA are displayed in Fig 4.1. Both the NMA and G/NMA LDHs exhibited high reflection peaks at  $10.96^\circ$ ,  $22.08^\circ$  and  $34.77^\circ$  with interplanar spacing of 8.06 Å, 4.02 Å and 2.58 Å and corresponding to 003, 006, and 009 planes respectively. The peaks at  $38.75^\circ$ ,  $45.7^\circ$ ,  $60.89^\circ$  and  $61.42^\circ$  are assigned to 015, 018, 110 and 113 planes respectively [69]. The result indicates the as-synthesized LDHs possess high crystallinity with well layered structure. Additional peaks at  $26.46^\circ$  corresponds to 002 plane [70] due graphene crystallinity was found in the G/NMA which indicates good integration of the graphene into the LDHs structure and this may inherently improve its adsorption performance. Calcination led to the elimination of physisorbed and interlayer H<sub>2</sub>O molecules, and interlayer anions with a resultant collapse of LDHs lamellar

structure. The result for the NMA-C and G/NMA-C shows the destruction of the LDHs structure after calcination with a resulting formation of mixed metal oxides MgO/NiO. Due to the relatively low temperature of calcination, no peaks assigned to any aluminium oxide specie such as spinel ( $\text{MgAl}_2\text{O}_4$ ) which crystallizes at high temperature and it indicates dispersion of  $\text{Al}^{3+}$  into the solid matrix solution of MgO [71-73]

Fig 4.2 depicts the characteristic FTIR spectra of a typical LDH. The broad between 3300-3800  $\text{cm}^{-1}$  is associated with the stretching vibrations of OH group of interlayer  $\text{H}_2\text{O}$  in the brucite- like layers [32]. This band becomes attenuated upon the calcination of the hydrotalcite. The weak band at 1640  $\text{cm}^{-1}$  corresponds to bending vibrations of OH of water molecules. The strong band at 1350 $\text{cm}^{-1}$  LDH which shift to weak band at 1390 $\text{cm}^{-1}$  indicates antisymmetric vibrations associated with Nitrate ions. Though this band attenuated, it was not completely removed indicating removal of the interlayer anion and a collapse of the LDH as (confirmed from XRD patterns). Peaks associated with carbonate are located around 1000-1100  $\text{cm}^{-1}$  (bending non-polar mode), 800-900  $\text{cm}^{-1}$  (torsion mode), 600-700  $\text{cm}^{-1}$  (bending angular mode) [33]. The M-O, M-O-M and O-M-O peaks are found below 1000  $\text{cm}^{-1}$ .

Fig 4.3 shows the microstructure of the asynthesized NMA, G/NMA, NMA-C, and G/NMA. The NMA comprises of small particles which aggregate to form platelet morphology. Addition of graphene to LDH resulted in overlapping nanosheets in G/NMA. Upon calcination, rough, compact and homogeneous surfaces comprising of nanoparticle formed. The calcined samples display larger pores which can facilitate the adsorption process.

Fig 4.1 XRD of NMA, G/NMA, NMA-C, and G/NMA-C.

Fig 4.2 FTIR spectra of NMA, G/NMA, NMA-C, and G/NMA-C.

**Fig 4.3 SEM of (A) NMA (B) G/NMA (C) NMA-C and (D) G/NMA-C.**

Fig 4.4 depicts the thermogravimetric analysis (TGA) which shows the decomposition pattern and thermal stability of the LDHs and its graphene hybrid. Three stages of weight loss occur under the thermal treatment up to temperature of 800°C. Physisorbed and intercalated water molecules are removed up to a temperature of 170°C with a resultant weight loss of 11.5% and 10.5% for NMA and G/NMA respectively. At the second stage, 23.5% for NMA and 22% for G/NMA in weight loss occur between 170°C and 370°C. This was due to decarbonation, dehydroxylation and elimination of other interlayer anions [74]. The second weight loss resulted into formation of mixed metal oxides (MMO). Thermal treatment above 370°C with little weight loss led to continuous decarbonation and decarboxylation and more formation of MMO. The total weight loss upon thermal exposure suggest good thermal stability of the synthesized material with G/NMA possessing better higher stability

## **4.2 Adsorption Parameters**

Effects of parameters such as pH, contact time, adsorbent dosage, EBT concentration and temperature were studied

### **4.2.1 Effect of Initial pH**

The surface charge as well as degree of ionization of adsorbate of the adsorbent is a major effect of pH which controls adsorption processes [41, 45]. The influence of pH (range of 2 to 8) on removal of EBT was carried using 0.01g of adsorbate in 30ml of 40mg/L dye solution operated at 180 rpm and 25°C for 8hrs. The result of Fig 4.5 shows that removal reduces as pH increase until 4 after which the removal efficiency decreases except for calcined G-LDH which maintains a relatively constant percentage removal at higher pH

Fig 4.4 TGA of NMA and G/NMA

Fig 4.5 Effect of pH on percentage removal of EBT

values. This can be a significant advantage in the practical use of calcined G-LDH in dyes removal due to its pH independence when compared to other adsorbents which performances significantly depend on pH adjustment. The maximum percentage removal recorded for NMA, G/NMA, NMA-C and G/NMA-C are 88.8, 92.3, 96.5 and 99.3 % respectively. The higher dye removal experienced by graphene hybrids were due to increased surface area contribution of the graphene. At very low pH, the structure of the layered material becomes impaired resulting in instability and leads to dissolution of the adsorbate and this reduces the adsorption performance of the adsorbates [75-77]. At higher pH values, increasing competition of  $\text{OH}^-$  for adsorption sites reduces removal of the anionic dye [69]. The optimum pH for the adsorption study was 4 and this was used for the rest of the experiment.

#### **4.2.2 Effect of Contact Time**

Fig 4.6 shows the influence contact plays on percentage removal of EBT for time range of 0 to 480 min. The percentage removal rises with increase in the contact time with rapid sorption in the first 15 minutes. This is an indication of strong polarity of the LDH surface to rapidly attract high number of dye molecule enhanced by large surface area [78]. Thereafter the rate gradually reduced until equilibrium was established at 240, 180, 90 and 60 min for fresh samples of NMA, NMA-C, G/NMA and G/NMA-C respectively. The faster adsorption rate of the graphene hybrid compared to the non-hybrid may be due to higher surface area. The higher adsorption rate of calcined sample when compared to uncalcined sample can be attributed to memory effect [15, 79]. The highest adsorption rate demonstrated by G/NMA-C shows synergistic interaction of graphene hybridization and calcination [79].

Fig 4.6 Effect of contact time on percentage removal of EBT. Adsorbent dosage 10mg;  $C_0 = 40 \text{ mgL}^{-1}$

### **4.2.3 Effect of Dosages**

Fig 4.7 displays the effect of adsorbents NMA, G/NMA, NMA-C and G/NMA-C dosages on adsorption of EBT. From the plot, two stages of adsorption are established. The first stage shows increase in EBT removal with a rise in adsorbent dosage. This is related with increase in active adsorption sites with increased supply of adsorbent. The second stage involves occurrence of a plateau signifying no further increase in adsorption with increased dosage. This indicated that the number of adsorption sites more than satiates the available number of dye molecules. As shown, the calcined samples recorded higher adsorption performance with increased dosage when compared to its uncalcined counterpart. Likewise, the hybrid shows better performance than the nonhybrid which may be associated to increased surface area. An increase of adsorbent dosage from 2mg to 10mg resulted in percentage increase of EBT adsorption from 6, 23, 11 and 36% to 87, 91, 96, and 99 % for NMA, G/NMA, NMA-C and G/NMA-C respectively. Except for calcined G-LDH whose percentage removal plateaus at 10mg, G/NMA show increased adsorption with adsorbent dosage while both NMA and NMA-C establish a plateau at 15mg for removal of 92 and 99% EBT respectively. This shows superior advantage of calcined G-LDH which possesses synergistic properties of hybridization and calcination. For subsequent experimental study, 10 mg of adsorbent was used.

### **4.2.4 Effect of Initial EBT Concentration**

Fig 4.8 shows the effect of initial EBT concentration on percentage removal of dye. As the initial concentration of dye increases, the percentage removal reduces. Since adsorbent dosage is fixed, the number of adsorption sites are fully satiated with dyes molecules

**Fig 4.7 Effect of Dosage on percentage removal of EBT. Contact time= 180mins;  $C_0 = 40 \text{ mgL}^{-1}$**

**Fig 4.8** Effect of concentration on percentage removal of EBT. Contact time= 180mins; Adsorbent dosage= 10 mg

rendering more dye molecules unadsorbed as the initial dye concentration is increased. This thus translates to a reduction on percentage removal with increase in initial dye concentration [69]. The percentage removal of EBT decreased from 87.8, 91.1, 96.1, and 99.9 % to 34.0, 64.9, 69.0 and 93.3% for NMA, G/NMA, NMA-C and calcined G/NMA-C respectively for change in concentration from 45 mg/L to 110 mg/L. The result further confirms that the graphene with LDH resulted in higher performance in adsorbing EBT. The surface of composites as confirmed from FTIR and XRD results improved the interaction of composite with EBT

### 4.3 Isotherm Studies

Adsorption isotherm is an indication of extent of distribution of adsorbate between the liquid phase and solid phases upon reaching equilibrium in the adsorption process [43]. In this study, three different temperatures and two well-established isotherm models, Langmuir isotherm and Freundlich isotherm, are considered.

The experimental data are fitted to the linear forms of Langmuir isotherm model (equation 2.6) and Freundlich isotherm model (equation 2.9) and the parameters obtained are shown in Table 4.1. The Langmuir isotherm with correlation coefficient  $> 0.98$  fits the experimental data in comparison to Freundlich isotherms for all the adsorbents and temperature under consideration. The maximum adsorption capacity computed at 25°C from the Langmuir model are 156.25, 263.16, 238.14 and 384.62 mg/g for NMA, G/NMA, NMA-C and calcined G/NMA-C respectively. The value of  $1/n < 1$  found in table 1 further buttress the suitability of Langmuir isotherm in describing the adsorption process [80]. This is indicative of a homogeneous surface accompanied by monolayer adsorption. The value of  $R_L < 1$  for all the sample shows that the adsorption is favorable.

**Table 4.1 Parameters of Isotherm models for adsorption of EBT**

| Sample  | T (K) | Langmuir        |        |        | Freundlich |        |        |
|---------|-------|-----------------|--------|--------|------------|--------|--------|
|         |       | $Q_m$<br>(mg/g) | $R_L$  | $R^2$  | $K_F$      | $1/n$  | $R^2$  |
| NMA     | 298   | 156.25          | 0.0350 | 0.9922 | 104.1838   | 0.0666 | 0.6998 |
|         | 308   | 136.97          | 0.0265 | 0.9974 | 98.3105    | 0.0572 | 0.9677 |
|         | 323   | 126.97          | 0.0307 | 0.9991 | 84.1589    | 0.0712 | 0.9941 |
| G/NMA   | 298   | 263.16          | 0.0310 | 0.9922 | 95.8959    | 0.2165 | 0.8661 |
|         | 308   | 256.41          | 0.0678 | 0.9794 | 94.0156    | 0.1798 | 0.9530 |
|         | 323   | 217.39          | 0.0673 | 0.9921 | 90.3026    | 0.1595 | 0.9707 |
| NMA-C   | 298   | 238.1           | 0.0220 | 0.9933 | 146.7912   | 0.1146 | 0.9643 |
|         | 308   | 204.23          | 0.0190 | 0.9842 | 122.5180   | 0.0971 | 0.9911 |
|         | 323   | 188.68          | 0.0176 | 0.9882 | 107.1026   | 0.1113 | 0.9687 |
| G/NMA-C | 298   | 384.62          | 0.0020 | 0.9955 | 283.7919   | 0.0762 | 0.9830 |
|         | 308   | 370.37          | 0.0180 | 0.9977 | 248.4277   | 0.0802 | 0.9749 |
|         | 323   | 322.58          | 0.0241 | 0.9974 | 227.2480   | 0.0697 | 0.9734 |

#### 4.4 Kinetic Studies

To predict feasible sorption process mechanism, adsorption rates were investigated using both pseudo-first order and pseudo-second kinetic models [63]. The kinetic data are fitted to the linear forms of the pseudo-first order (equation 2.13) and pseudo-second order (equation 2.14) models. The kinetic parameters calculated from the linear regression and the correlation coefficients are summarized in Table 4.2. The high correlation coefficient  $R^2$  obtained from pseudo-second model indicates its suitability when compared to the pseudo-first order model. In addition the  $q_{e,cal}$  obtained from the pseudo-second order model was close to the experimental value,  $q_{e,exp}$ . This is an indication of suitability of the pseudo-second order model in characterising the adsorption of EBT on the materials.

#### 4.5 Effect of Temperature and Thermodynamic studies

Thermodynamic study was undertaken to know the effects of temperature on the adsorption process via changes in enthalpy ( $\Delta H$ ), Gibbs free energy ( $\Delta G$ ) and entropy ( $\Delta S$ ) according to the following relation

$$\Delta G = -RT \ln K_D \quad 4.1$$

$$\ln K_D = \frac{\Delta S}{R} - \frac{\Delta H}{RT} \quad 4.2$$

where  $K_D$  defines distribution coefficient,  $T$  is absolute temperature and  $R$  is molar gas constant. The thermodynamic variables are documented in Table 4.3. The adsorption of EBT on all the as-synthesized samples is thermodynamically feasible and spontaneous with strong affinity between the adsorbate and the adsorbents as indicated by a negative value of  $\Delta G$  [81]. In addition, the adsorption is exothermic as the adsorption performance

**Table 4.2 Parameters of kinetic models**

| Adsorbent | Pseudo first order |             |        |       | Pseudo second order |                 |       |
|-----------|--------------------|-------------|--------|-------|---------------------|-----------------|-------|
|           | $q_e$ (exp)        | $q_e$ (cal) | $k_1$  | $R^2$ | $q_e$ (cal)         | $k_2 * 10^{-2}$ | $R^2$ |
| NMA       | 118.50             | 72.23       | 0.0060 | 0.95  | 111.11              | 2.95            | 0.99  |
| G/NMA     | 124.76             | 37.162      | 0.0067 | 0.95  | 120.48              | 8.87            | 0.99  |
| NMA-C     | 134.34             | 106.29      | 0.0081 | 0.93  | 161.29              | 0.76            | 0.96  |
| G/NMA-C   | 137.02             | 39.26       | 0.0108 | 0.90  | 138.88              | 7.86            | 0.99  |

**Table 4.3 Thermodynamics Parameters for adsorption of EBT**

| Sample  | T(k) | $K_d$ | $\Delta G$ | $\Delta H$ | $\Delta S$ |
|---------|------|-------|------------|------------|------------|
| NMA     | 298  | 14.38 | 6.60       | -10.63     | -14.08     |
|         | 308  | 10.42 | 6.00       |            |            |
|         | 323  | 10.13 | 6.23       |            |            |
| NMA-C   | 298  | 11.07 | 5.96       | -20.01     | -46.62     |

declines with increase in temperature as noticed with a negative  $\Delta H$ . The negative  $\Delta S$  indicated higher order of reaction took effect on adsorption of EBT on the samples.

#### **4.6 Adsorption Mechanism**

Fig 4.9 shows the XRD of the used adsorbents which shows a slight shift in the positions of diffraction peaks when compared to fresh samples (Fig 1). This suggest partial intercalation of EBT into the structure with a removal via surface adsorption. The XRD patterns of used calcined samples display peaks assigned to  $d_{003}$  and  $d_{006}$  similar original LDHs XRD patterns which forms through rehydration and surface reconstruction upon contact with aqueous solution. The peaks were broad with decreased intensity implying reduced crystallinity. The calcined samples regained their original LDHs structure through memory effect upon rehydration. Structural reconstruction via ‘memory effect’ with partial intercalation of anionic species along with surface adsorption forms the basis of dye removal by calcined LDH and hybrid.

Fig 4.10 shows the FTIR of the spent adsorbent which display that the bands were weak especially the strong nitrate band. This suggest anion exchange of  $\text{NO}_3^-$  by dye molecules. Other additional peaks observed were from EBT and this shows that the dye was adsorbed onto the surfaces of the adsorbents. Fig 4.11 shows microstructure of samples after EBT adsorption. It is vivid that the irregularly shaped rough surfaces transform to smooth surfaces with slight irregularities. A closer look at the SEM images of Fig 4.13 shows the incorporation of EBT onto the LDH, hybrid LDH and its calcined nanocomposites. It is proposed that mechanism behind the adsorption process are ion exchange and surface adsorption for uncalcined samples while structural reconstruction, ion exchange and surface adsorption were involved for the calcined samples.

**Fig 4.11 SEM of spent (A) NMA (B) G/NMA (C) NMA-C and (D) G/NMA-C.**

#### **4.7 Regeneration and Reuse of Adsorbents**

Regeneration and reuse account for substantial part (> 70%) of operating and maintenance cost [82, 83], hence great consideration is given towards choosing materials for economic feasibility of any process. Due anionic nature of the dye, alkaline solution can desorb the dyes molecules by weakening the electrostatic attraction between the surfaces of adsorbents and the dye [84]. 0.1M NaOH solution was employed to regenerate the LDHs and graphene hybrid. In addition to the basic treatment, calcination at 500<sup>0</sup>C for 4h under nitrogen environment was used to regenerate the calcined NiMgAl and its graphene hybrid. For subsequent regeneration, the same desorption and calcination treatments were employed. Fig 4.12 shows EBT dye removal after each cycle reuse and regeneration. On NMA, the percentage of EBT removed decreased from 88% to 81% in the first 2 cycles and reached 57% at the end of the fourth cycle. G/NMA reached 74% removal efficiency at the end of the fourth cycle. This less reduction may be due to the influence of graphene in the LDH structure. After regeneration, lower peaks were observed implying decreased crystallinity of LDHs which explains the reduction in adsorption performance. Calcination helped improved the recovery of the adsorbent as calcined NiMgAl and Graphene-NiMgAl had percentage removal of 80% and 87% at the end of the forth cycle. This implies the regeneration of the adsorbents were efficient and they could be deployed as affordable reusable adsorbents.

#### **4.8 Comparison with Other adsorbents**

Table 4.4 compares the maximum adsorption capacity of the adsorbents synthesized in the work with other conventional adsorbents previously reported in literature. It clearly shows that those from this work exhibit superior performances that others, implying it could be

deployed for the remediation of anionic dye contaminated water. The higher performances may be attributed to the synthesis techniques which facilitated the formation of abundant function groups of oxygen and higher surface area resulting from calcination [90, 91] was further improved by hybridizing the LDHs with graphene.

## CHAPTER 5

### Graphene/ Ternary Layered Double Hydroxide

#### Nanocomposites For Efficient Removal Of Methyl Orange From

#### The Aqueous Phase

The chapter reports the result of adsorption of Methyl orange (MO) on the ternary LDH and its nanocomposite from the aqueous phase. For simplicity, uncalcined MgCoAl, calcined MgCoAl, uncalcined graphene-MgCoAl and calcined Graphene-MgCoAl are referred to as MCA, MCA-C, G/MCA and G/MCA-C respectively.

#### 5.1 Characterization of MCA, G/MCA, MCA-C and G/MCA-C

LDHs possess unique characteristic diffraction peaks [69, 92] which are well established in the ternary LDH as presented in Fig 5.1. The intensity of the symmetric peak at  $11.36^\circ$  assigned to the (003) plane indicates a well-defined crystalline structure with associated basal spacing of 0.775nm. The other peaks at  $2\theta = 22.9^\circ, 34.5^\circ, 38.9^\circ, 45.5^\circ, 60.3^\circ$ , and  $61.5^\circ$  are indexed to the (006), (009), (015), (018), (110) and (113) respective planes. The pristine graphene shows its peak at  $26.84^\circ$   $2\theta$  assigned to the 002 plane [70, 93]. The G/MCA maintains a similar structure to MCA due to the occurrence of similar 110 and 113 peak planes [94] but with graphene induced broadness in the (003) and (006) planes of G/MCA. The broadness may be ascribed to the occurrence of electrostatic interaction in the composite which affected the nucleation and crystallize size of the LDH [95]. Similar observations have been previously reported [94]. Upon calcination, the LDHs peaks

Fig 5.1 XRD of MCA, G/MCA, MCA-C, and G/MCA-C

become alienated due to destruction of its structure resulting in formation of mixed metal oxides (MMO) known with peaks located at the (111), (200) and 220 planes [10, 52].

FTIR analysis is an important tool to help understand the active sites and interactions of group responsible for the adsorption. Fig 5.2 depicts the FTIR of MCA, G/MCA, MCA-C and G/MCA-C. For MCA and G/MCA, the peaks between 3400 and 3600  $\text{cm}^{-1}$  are assigned to the stretching modes of the interlayer water molecule while the bending modes of water are located at 1640  $\text{cm}^{-1}$  [96]. In addition, the interlayer anions ( $\text{NO}_3^-$ ) have a stretching peak at 1350  $\text{cm}^{-1}$  while the peaks below 1000  $\text{cm}^{-1}$  corresponds to the metal-oxygen vibration bond [92]. Vibration relating to the C-O-C bond is located at 1040  $\text{cm}^{-1}$ . Calcination led to removal of interlayer and physisorbed water molecules and interlayer anions and this is evident in peak reduction in both MCA-C and G/MCA-C. This further confirm the alteration of the structure of the LDHs as previously established by XRD. Calcination helps with more production of oxygen containing functional groups which is expected to profoundly increase the MO adsorption capacity [97].

Thermal behaviors and temperature dependent decomposition patterns of the synthesized samples were investigated by thermogravimetry analysis (TGA) under nitrogen environment up to 800°C as shown in Fig 5.3. MCA and G/MCA experience three modes of weight losses which resulted in total weight reduction by 39% and 37.7% respectively. Physisorbed and intercalated water molecules are removed up to a temperature below 200°C in the first stage [98] and this accounts for 10.4 and 8.5% loss. This is subsequently followed by dihydroxylation (DH), decarbonation (DC) and removal of other interlayer anions such as nitrates in the second stage of weight loss between 200°C and 400°C and this resulted in 23.3 % loss for both. The third stage involves little weight beyond 400°C

Fig 5.2 FTIR of MCA, G/MCA, MCA-C, and G/MCA-C

**Fig 5.3** TGA of MCA, G/MCA, MCA-C and G/MCA-C

with further decarbonation and dehydroxylation results in production of mixed metal oxides (MMO) [99]. MCA-C and G/MCA-C experience two modes of weight reduction which are mainly due to DC and the interlayer anions removal and formation of MMO. Most of the water molecules have being eliminated due to calcination. Between (35°C and 40°C), both MCA-C and G/MCA-C gained weight due to absorption of water molecules from the environment and these were subsequently removed with increase in temperature

The SEM microstructures images of the adsorbent samples are shown in Fig 5.4. The SEM of MCA shows large numbers of loose flower-like nanoparticles which are uniformly distributed. The morphology observed is a result of the synthesis route which has previously been reported [100]. Introduction of graphene to form G/MCA resulted in the formation of irregularly shaped plate-like nanosheets with overlapping configuration. The calcination resulted in the formation of the adsorbents with rough and compact surfaces.

## **5.2 Adsorption Parameters**

Effects of parameters such as pH, contact time, adsorbent dosage, EBT concentration and temperature were studied

### **5.2.1 Effect of Initial pH**

The surface charge, active sites dissociation of functional group of the adsorbent, extent of ionization and structure of the dye molecules are predominantly affected by pH [41, 45]. The percentage dye removal dependence on pH when the pH was varied from 3 to 9 is shown in Fig 5.5 (A) meanwhile Fig 5.5 (B) displays the point of zero charge ( $pH_{PZC}$ ) of MCA, G/MCA, MCA-C and G/MCA-C determined by the drift method [73]. The  $pH_{PZC}$  of MCA, G/MCA, MCA-C and G/MCA-C are 4.99, 5.17, 5.94 and 5.94 respectively. The

**Fig 5.4 SEM of (A) MCA, (B) G/MCA, (C) MCA-C, and (D) G/MCA-C**

**Fig 5.5 (A) Effect of pH on percentage removal of MO at 298K.  $C_0 = 30$  mg/L; dosage = 10 mg (B)  $pH_{pzc}$  for MCA, G/MCA, MCA-C and G/MCA-C**

MO percentage removal was observed to decline for a rise in pH from 3 to 9 and this trend is experienced by all the adsorbents. Similar behavior were associated with other LDH as reported elsewhere [98].

Surface charges of the adsorbents in the aqueous medium can be used to substantiate this behavior. For pH 3 below the  $pH_{PZC}$ , the adsorbents possess positively a charged surface (protonated) which enhances electrostatic attraction to negatively charged molecules of the anionic dyes. Hence, the highest removal of the dye of 83, 88, 96 and 98% for MCA, G/MCA, MCA-C and G/MCA-C respectively, was achieved at pH 3. As the pH increased to pH 4 and above, there was a reduction in the number of positively-charged adsorption sites leading to decreased removal of MO molecules. Furthermore, increasing the pH beyond  $pH_{PZC}$  led to formation of a negatively charged adsorption surface which stimulates electrostatic repulsion between the anionic dye molecules and adsorbents. However, at a higher pH ( $\gg pH_{PZC}$ ), increased competition between dyes molecules and  $OH^-$  in aqueous solution in addition to electrostatic repulsion profoundly reduced the percentage dye removal [15]. Consequently, pH 3 was used for the subsequent adsorption studies presented below.

### **5.2.2 Effect of Dosage**

The variability of percentage MO removal when MCA, MCA-C, G/MCA and G/MCA-C adsorbents dosages were varied from 2 mg to 25 mg is shown in Fig 5.6. The percentage removal increases with increase in adsorbent dosage for all the adsorbents. The percentage removal increased from 28, 31, 51, and 57% to 72, 78, 92, and 96% for a change in dosage from 2 mg to 8mg for MCA, MCA-C, G/MCA and G/MCA-C respectively. These increments can be ascribed to increased supply of active adsorption sites. The highest

**Fig 5.6** Effect of dosage on percentage removal of MO at 298K. Contact time= 180mins;  $C_0 = 30$  mg/L

adsorption was experienced by G/MCA-C. This was attributed to the interplay of graphene introduction and calcination considering that the least removal was associated with the MCA. Beyond 10mg, there was a differential change in percentage removal of the MO with dosage which indicates the saturation of the quantity of MO molecules by the increased active adsorption sites. Thus, 10 mg was selected as the optimum dosage and was used for subsequent experimentation.

### **5.2.3 Effect of Contact time**

The influence of contact time varied from 15 minutes to 1440 minutes on percentage removal of MO for all the MCA, G/MCA, MCA-C and G/MCA-C is shown in Fig 5.7. All four adsorbents exhibited fast sorption in the first 15 minutes with measured removal efficiency of 60, 67, 57 and 85 % for MCA, G/MCA, MCA-C and G/MCA-C respectively. The MO removal increased with higher contact time until equilibrium was established at 240, 240, 180 and 180 minutes for MCA, G/MCA, MCA-C and G/MCA-C respectively. The fast adsorption of calcined samples in the first few minutes can also be attributed to memory effect [79]. The higher adsorption of G/MCA over MCA can be ascribed to the contribution of graphene which improved the properties of the nanostructured G/MCA. However, the higher adsorption of MCA-C over MCA was attributed to calcination which enhances the availability of oxygen carrying functional groups. Thus, both the interplay of graphene introduction and calcination leads to the highest adsorption experienced by the G/MCA-C. In addition, the abundance of oxygen-carrying functional group also contributes to fast adsorption of the dye [98].

**Fig 5.7** Effect of contact time on percentage removal of Methyl orange. Adsorbent dosage 10mg;  $C_0 = 30$  mg/L

#### **5.2.4 Effect of initial MO concentration**

Influence of initial dye concentration on percentage removal of MO is depicted in Fig 5.8. The plot shows that there was reduction in percentage removal as initial concentration was increased. When the MO concentration was increased at a fixed adsorbent dosage, active sites were also fixed in number are occupied and free active binding sites are continuously been filled up. Hence, unadsorbed dye molecules are left in the solution after complete occupation of adsorption sites. At 30 mg/L MO concentration, the percentage removal of MO of 83, 88, 96 and 98 were significantly, decreased to 60, 65, 75% and 77% when the concentration was increased to 150 mg/L for MCA, G/MCA, MCA-C and G/MCA-C, respectively, for a fixed dosage of 10 mg for a contact time of 180 min. Further increases in the MO concentration induced more reduction in the MO percentage removal. As previously observed, G/MCA-C experienced the highest adsorption of all initial MO concentrations due to the synergistic interplay previously explained.

#### **5.3 Adsorption Isotherm**

An adsorption isotherm study is significant in designing adsorption system due to its importance in estimating the adsorbent adsorption capacity as well as analyzing interaction between adsorbate and adsorbent at equilibrium [77]. Thus, two common adsorption isotherm models, Langmuir and Freundlich, are used to model the four investigated adsorbents adsorption processes. The Langmuir isotherm is considered accurate on the premise that the adsorption occurred on monolayer surfaces with equivalent energies, no interaction occurred among adsorbed molecules and the same adsorption mechanism is experienced by all molecules [36]. The Langmuir model is given as

**Fig 5.8** Effect of concentration on percentage removal of MO at 298K. Contact time= 180mins; adsorbent dosage= 10 mg

$$q_e = \frac{q_m b C_e}{1 + b C_e} \quad 5.1$$

Where  $q_m$  (mg/g) and  $b$  (L/mg) are Langmuir constants signifying maximum monolayer adsorption capacity and a parameter relating to free energy of adsorption respectively[41].

Linearizing equation 5.1 gives

$$\frac{C_e}{q_e} = \frac{1}{b q_m} + \frac{C_e}{q_m} \quad 5.2$$

The value of  $b$  and  $q_m$  are obtained from the intercept and slope respectively of the linear plot of  $C_e$  versus  $q_m$  in equation 5.2. Another parameter termed the separation factor,  $R_L$ , defined in Chen et al. [60] signifies unfavourable, linear, favourable, and irreversible adsorption at  $R_L > 1$ ,  $R_L = 1$ ,  $0 < R_L < 1$  and  $R_L = 0$  respectively.

$$R_L = \frac{1}{1 + b C_0} \quad 5.3$$

On the other hand, the Freundlich isotherm assumes a multi-layered heterogeneous adsorption with heat of adsorption distribution [43] and its non-linear and linear forms are given in equation 7 and equation 8, respectively.

$$q_e = K_F C_e^{1/n} \quad 5.4$$

$$\log q_e = \log K_F + \frac{1}{n} \log C_e \quad 5.5$$

Where  $n$  and  $K_f$  are Freundlich constants indicating adsorption intensity and distribution coefficient relating to bonding energy respectively [69].  $1/n < 1$  indicates a normal Langmuir isotherm while  $1/n > 1$  is cooperative adsorption [80]. The value of  $1/n$  and  $K_F$

are obtained from the slope and intercept, respectively, of the linear plot of  $\log q_e$  versus  $\log C_e$  in equation 5.5.

Table 5.1 shows the parameters of adsorption of both Langmuir and Freundlich isotherms models. It is apparent that the correlation coefficient of the Langmuir model ( $R^2 > 0.98$ ) is higher than that of the Freundlich model indicating that the former more closely fits the adsorption process when compared to the latter. This assertion was adequately, corroborated considering the values of  $1/n$  ( $1/n < 1$ ). Likewise, the values of  $R_L$  ( $0 < R_L < 1$ ) indicate the favorability of the adsorption process for all the four adsorbents. The drop in maximum adsorption capacity with increases in temperature indicates the unfavorability of the adsorption at higher temperatures. Moreover, the maximum adsorption capacity at 25°C is 357.14, 384.62, 400 and 434.78 mg/g for MCA, G/MCA, MCA-C and G/MCA-C, respectively. It can be concluded that the adsorption is majorly characterize by homogeneity as depicted by the close fit of the Langmuir model.

## 5.4 Adsorption Kinetics

Kinetic models are essential in predicting sorption rate and expressing a suitable reaction mechanism [101]. Thus, the linearized forms of both pseudo-first order (equation 5.6) and pseudo-second order (equation 5.7) models are fitted to the experimental data. The best model describing the MO adsorption kinetics for the adsorbents was determined by considering the model with highest coefficient of correlation ( $R^2$ )

$$\log(q_e - q_t) = \log q_e - \frac{k_1 t}{2.303} \quad 5.6$$

$$\frac{t}{q_t} = \frac{1}{k_2 q_e^2} + \frac{t}{q_e} \quad 5.7$$

**Table 5.1 Parameters of Isotherm models for adsorption of Methyl orange**

| Sample  | T<br>(K) | Langmuir        |        |        | Freundlich |        |        |
|---------|----------|-----------------|--------|--------|------------|--------|--------|
|         |          | $Q_m$<br>(mg/g) | $R_L$  | $R^2$  | $K_F$      | $1/n$  | $R^2$  |

|         | 308      | 384.62          | 0.0291 | 0.9829 | 62.1727    | 0.4805 | 0.9444 |
|         | 318      | 357.14          | 0.0655 | 0.9928 | 46.7951    | 0.4768 | 0.9198 |
| G/MCA-C | 298      | 434.78          | 0.0420 | 0.9783 | 106.6596   | 0.3570 | 0.9771 |
|         | 308      | 400.00          | 0.0337 | 0.9973 | 77.9292    | 0.4328 | 0.9246 |
|         | 318      | 370.37          | 0.0580 | 0.9961 | 52.7715    | 0.4655 | 0.9347 |

Where  $k_1$  ( $\text{min}^{-1}$ ) and  $k_2$  ( $\text{g mg}^{-1} \text{min}^{-1}$ ) are constants from pseudo-first order and pseudo-second order models respectively. Both constants are obtained from the linear regression of their respective equations. The parameters of both models are contained in Table 5.2. From the tabulated result, it is deduced that the pseudo-second order model ( $R^2 > 0.99$ ) adequately fits the experimental data. Also, the maximum adsorption capacity from the pseudo-second order model closely matches the experimental value. It can be stated that rate controlling mechanism of the adsorption is predominated by chemisorption which is the basic assumption the pseudo-second order model was built on [102]. Similar results have been published indicating chemisorption as the controlling step in removal of many dyes by LDHs [33, 98, 100, 101].

## 5.5 Thermodynamics and Effect of Temperature

The effect of temperature and change in internal energy relating to adsorption processes are important and they can be provided from thermodynamic consideration through changes in enthalpy ( $\Delta H$ ), Gibb's free energy ( $\Delta G$ ) and entropy ( $\Delta S$ ) according to the following relationship,

$$\Delta G = -RT \ln K_D \quad 5.8$$

$$\ln K_D = \frac{\Delta S}{R} - \frac{\Delta H}{RT} \quad 5.9$$

Where  $R$  ( $8.314 \text{ J/mol/K}$ ) is the molar gas constant and  $T$  ( $\text{K}$ ) is the absolute temperature ( $\text{K}$ ).  $K_D$  ( $\text{L/g}$ ) is a thermodynamic equilibrium constant obtained by plotting  $\ln(q_e/C_e)$  versus  $q_e$  and extrapolating  $q_e$  to zero [103].  $\Delta G$  is estimated from equation 11 while  $\Delta H$  and  $\Delta S$  are computed from the slope and intercept of the linear plot of  $\ln K_D$  versus  $1/T$  in equation 12.

**Table 5.2 Parameters of Kinetic models**

| Adsorbent | Pseudo first order |              |         |        | Pseudo second order |                 |        |

| G/MCA-C   | 104.607            | 12.779       | 0.0145  | 0.8921 | 105.263             | 0.3432          | 0.9999 |

In this study, three temperatures (298K, 308K and 318K) are considered to estimate the thermodynamic parameters. The values of the thermodynamic parameters are presented in Table 5.3 and the linear graph of  $\ln K_D$  versus  $1/T$  is shown in Fig 5.9.

Thus, these results indicate that the adsorption of MO by all the tested adsorbents is characterized by feasibility and spontaneity (negative  $\Delta G$ ) and are exothermic in nature (negative  $\Delta H$ ). This implies a decrease in adsorption and reduced spontaneity with increases in temperature as further suggested by the decreasing  $K_d$  being in agreement with increasing  $\Delta G$  with increasing temperature [32, 103]. The negative values of  $\Delta S$  for the four samples are an indication of reduced randomness at the adsorbate/adsorbent interface and greater order of reaction associated with adherence of the dye on the surface of the adsorbents with a resultant reduction of the system's degree of freedom [104, 105].

## 5.6 Adsorption Mechanism

FTIR and XRD analyses of the spent MCA, G/MCA, MCA-C and G/MCA-C adsorbents were undertaken to understand the interaction of active sites on the adsorbent and functional groups of the dyes which can help better understand the adsorption mechanism [106, 107]. From the FTIR results obtained as shown in Fig 5.10, it is obvious that new peaks appeared after the MO adsorption on all the adsorbents. A New band at  $1118\text{ cm}^{-1}$  correspond to the C-N bond vibration while the band at  $1031\text{ cm}^{-1}$  is ascribed to the symmetric stretching vibration of the  $-\text{SO}_3^-$  of the MO [106, 108, 109]. This suggest that molecules of the MO dye are fastened on the surfaces of the adsorbents and that electrostatic interaction was involved in the process. It is also apparent that the peak of the  $\text{NO}_3^-$  vibration located at  $1350\text{ cm}^{-1}$  on fresh adsorbents attenuated and slightly shifted to a higher wavenumber on the used adsorbents suggesting chemical interaction. The reduction

**Table 5.3 Thermodynamic parameters for adsorption of Methyl orange**

| Sample  | T(k) | $K_d$ | $\Delta G$ | $\Delta H$ | $\Delta S$ |
|---------|------|-------|------------|------------|------------|

|         | 308  | 3.360 | -3.103     |            |            |
|         | 318  | 3.011 | -2.914     |            |            |
| MCA-C   | 298  | 4.761 | -3.866     | -11.059    | -24.124    |
|         | 308  | 4.141 | -3.639     |            |            |
|         | 318  | 3.595 | -3.383     |            |            |
| G/MCA-C | 298  | 5.649 | -4.290     | -15.179    | -36.559    |
|         | 308  | 4.600 | -3.908     |            |            |
|         | 318  | 3.843 | -3.559     |            |            |

Fig 5.9 Linear plot of  $\ln K_D$  vs  $1/T$

Fig 5.10 FTIR of spent MCA, G/MCA, MCA-C and G/MCA-C

of peaks assigned to the stretching and bending modes of interlayer water molecules is an indication that there was also contribution of hydrogen bonding in the adsorption process [110].

Fig 5.11 shows the XRD of the all the four spent adsorbents. Noticeably, no significant changes were observed in the peak positions of MCA and G/MCA except the changes related to diffractogram peak intensities indicating more random crystal deformation [107, 111]. This suggested that anion surface adsorption is one of the mechanism of adsorption as proposed by Wang and his group [112]. The spent MCA-C and G/MCA-C were reconstructed via a memory effect to their respective LDH. It can be construed that intercalation via reconstruction and rehydration play an important role in adsorption of the MO on the surfaces of the MCA-C and G/MCA-C [73]. Hence, the proposed mechanisms of adsorption for MCA and G/MCA are hydrogen bonding, surface adsorption, chemical and electrostatic interactions, while surface reconstruction along with hydrogen bonding, ion exchange, chemical and electrostatic interactions are involved for MCA-C and G/MCA-C.

## **5.7 Regeneration and reuse of adsorbents**

Economic feasibility of an adsorption process is highly influenced by adsorbent regeneration and reuse potentials which could account for saving of up to 70 % of the operation and maintenance costs [82, 83]. To regenerate the adsorbents tested in this study, 0.1 M NaOH slurries of the spent adsorbents were agitated continuously for 24 hours, filtered and washed several times with deionized water. This treatment was used for subsequent regeneration and reuse applications for the three investigated adsorption cycles.

Fig 5.12 shows the percentage MO removal for the three adsorption cycles. The percentage

Fig 5.11 XRD of spent MCA, G/MCA, MCA-C and G/MCA-C

**Fig 5.12** Percentage removal of MO dye after three regeneration cycles

removal decreased to 80, 84, 88 and 90 % on the second use for MCA, G/MCA, MCA-C and G/MCA-C, respectively. However, the third reuse showed little reduction in the removal efficiency to 78, 81, 87, and 88 %, respectively. This clearly indicates that all the adsorbents employed in this study are characterized by high regeneration and reusability potentials, thereby, showcasing their potentials for cost-effective deployment in the treatment of real water and wastewater for removal of dyes.

### **5.8 Comparison to other Adsorbents**

The performances of the MCA, G/MCA, MCA-C and G/MCA-C adsorbents in terms of the maximum achievable adsorption capacity are compared with other LDH reported in literature as highlighted in Table 4. These tested adsorbent materials perform better than most of the similar reported LDH which buttresses their huge potentials in water treatment applications.

**Table 5.4 Comparison of adsorption capacities of LDH for MO adsorption**

| <b>Adsorbent</b>                     | <b>q<sub>m</sub> (mg/g)</b> | <b>references</b> |

## CHAPTER 6

### CONCLUSION AND RECOMMENDATION

#### 6.1 Conclusion

This work focuses on deployment of adsorption process for water remediation with a focus on dye removal. Layered double hydroxides (LDHs), an anionic clay, was introduced as an adsorbent in use due to its excellent ion exchange capacity and large surface area. This work further reports the synthesis of ternary LDH and its graphene nanocomposite via coprecipitation route and were further calcined at 400<sup>0</sup>C for 3h for application in removal of EBT and MO from aqueous phase. Structural characterization of the nanocomposite by FTIR and XRD shows excellent integration of graphene and LDH. The characterization techniques also show the formation of layered double oxide (LDO) after calcination. Parametric study reveals fast sorption process optimized at acidic pH due to abundance of oxygen containing functional groups. It was revealed that adsorption on graphene hybrid is highly pH independent which makes it more promising for industrial application. The adsorption processes were suitably fitted by Langmuir isotherm with maximum adsorption computed to be 384.62 mg/g for EBT adsorption on G/NMA-C and 434.78 mg/g for adsorption of MO on G/NMA-C. The highest capacities obtained for the calcined graphene nanocomposites arise from the synergistic contribution of graphene integration and calcination.

Kinetics study indicates the suitability of pseudo-second order model than pseudo-first order due to chemisorption nature of the adsorption process. Thermodynamics study shows

the exothermic nature of the adsorption with lower adsorption at higher temperature. The adsorption mechanism involves surface adsorption, hydrogen bonding, chemical and electrostatic interaction. The adsorbents are easily recovered with high reusability indicating their potentials for the treatment of dye contaminated water. The calcined graphene hybrid shows superior performance when compared to others due to synergistic effect of hybridization and calcination resulting in large surface area.

## **6.2 Recommendation**

The following are recommended for future study

1. The synthesized materials should be applied to removal of cationic dyes while taking parametric study into consideration.
2. The synthesized materials should be applied to mixture of dyes to investigate simultaneous removability, optimal condition and preference
3. Other forms of nanocomposites such as Graphene/Bentonite/LDH, MWCNT/Bentonite/LDH, bentonite/ ternary LDH should be synthesized and their performance tested on both cationic and anionic dyes
4. The synthesized and recommended hybrids should be used in removal of heavy metals from aqueous phase
5. The synthesized and recommended hybrids should be tested in other purification schemes such desulfurization of wastewater and allied processes

## Vitae

Name : Taye Saheed Kazeem |

Nationality : Nigerian |

Date of Birth : 8/9/1988 |

Email : kazeemts@gmail.com |

Address : 86, Yaya Abatan street, Ogba-ijaiye, Lagos -100218, Nigeria |

Academic Background : B.Sc Chemical Engineering (2008-2013), First class honors

Obafemi Awolowo University, Ile-Ife, Nigeria

### Research Interest

- Nanomaterials synthesis
- Novel hybrid fabrication and characterization
- Wastewater treatment
- Renewable energy, thermal energy storage materials and phase change materials

### Publications

- Zubair, M.; Jarrah, N.; Ihsanullah; Khalid, A.; Manzar, M. S.; Kazeem, T. S.; Al-Harthi, M.
